

Class 28: Naming Local Procedures

Held: Monday, 10 March 2008

Summary: We explore why and how one writes local recursive procedures.

Related Pages:

- Reading: Local Procedure Bindings.

Notes:

- I am continuing to reserve our normal start-of-class time for comments on campus events.
- Are there questions on Exam 2?
- Tomorrow I leave for my conference after class, and won't have email access until Wednesday afternoon (or later). Please get questions to me before class!
- Reading for tomorrow: Numeric Recursion.

Overview:

- Why have local procedures.
- Creating local procedures with `letrec`.
- Creating local procedures with named `let`.
- An example: `reverse`.

Local Procedure Bindings

- Today's class will focus not on something new, but on a better way to do something old: Define helper procedures.
- We frequently want to define procedures that are only available to certain other procedures (typically to one or two other procedures).
- We call such procedures *local procedures*
- Most local procedures can be done with `let` and `let*`.
- However, neither `let` nor `let*` works for recursive procedures.
- When you want to define a recursive local procedure, use `letrec`.
- When you want to define only one, you can use a weird variant of `let` called "named `let`".

letrec

- A letrec expression has the format

```
(letrec ((name1 exp1)
        (name2 exp2)
        ...
        (namen expn))
  body)
```

- A letrec is evaluated using the following series of steps.
 - First, enter $name_1$ through $name_n$ into the binding table. (Note that no corresponding values are entered.)
 - Next, evaluate exp_1 through exp_n , giving you results $result_1$ through $result_n$.
 - Finally, update the binding table (associating $name_i$ and $result_i$ for each reasonable i).
- Not that its meaning is fairly similar to that of let, except that the order of entry into the binding table is changed.

Named let

- Named let is somewhat stranger, but is handy for some problems.
- Named let has the format

```
(let name
  ((param1 exp1)
   (param2 exp2)
   ...
   (paramn expn))
  body)
```

- The meaning is as follows:
 - Create a procedure with formal parameters $param_1 \dots param_n$ and body $body$.
 - Name that procedure $name$.
 - Call that procedure with actual parameters exp_1 through exp_n .
- Yes, that's right, we've packaged together the procedure definition and the procedure call.
- In effect, we're just doing

```
(letrec ((name (lambda (param1 ...
                  paramn)
                body)))
  (name val1 ... valn))
```

An Example

- As an example, let's consider the problem of writing `reverse` (which I hope you recall from the exam).
- A first version, without local procedures

```
(define reverse
  (lambda (lst)
    (reverse-kernel lst null)))
(define reverse-kernel
  (lambda (remaining so-far)
    (if (null? remaining)
        so-far
        (reverse-kernel (cdr remaining) (cons (car remaining) so-far)))))
```

- The principle of encapsulation suggests that we should make `reverse-kernel` a local procedure.

```
(define reverse
  (letrec ((kernel
            (lambda (remaining so-far)
              (if (null? remaining)
                  so-far
                  (kernel (cdr remaining) (cons (car remaining) so-far)))))
    (lambda (lst)
      (kernel lst null))))
```

- The pattern of “create a kernel and call it” is so common that the named `let` exists simply as a way to write that more concisely.

```
(define reverse
  (lambda (lst)
    (let kernel ((remaining lst)
                 (so-far null))
      (if (null? remaining)
          so-far
          (kernel (cdr remaining) (cons (car remaining) so-far)))))
```

Lab

- Start the lab.
- Finish it on your own time.
